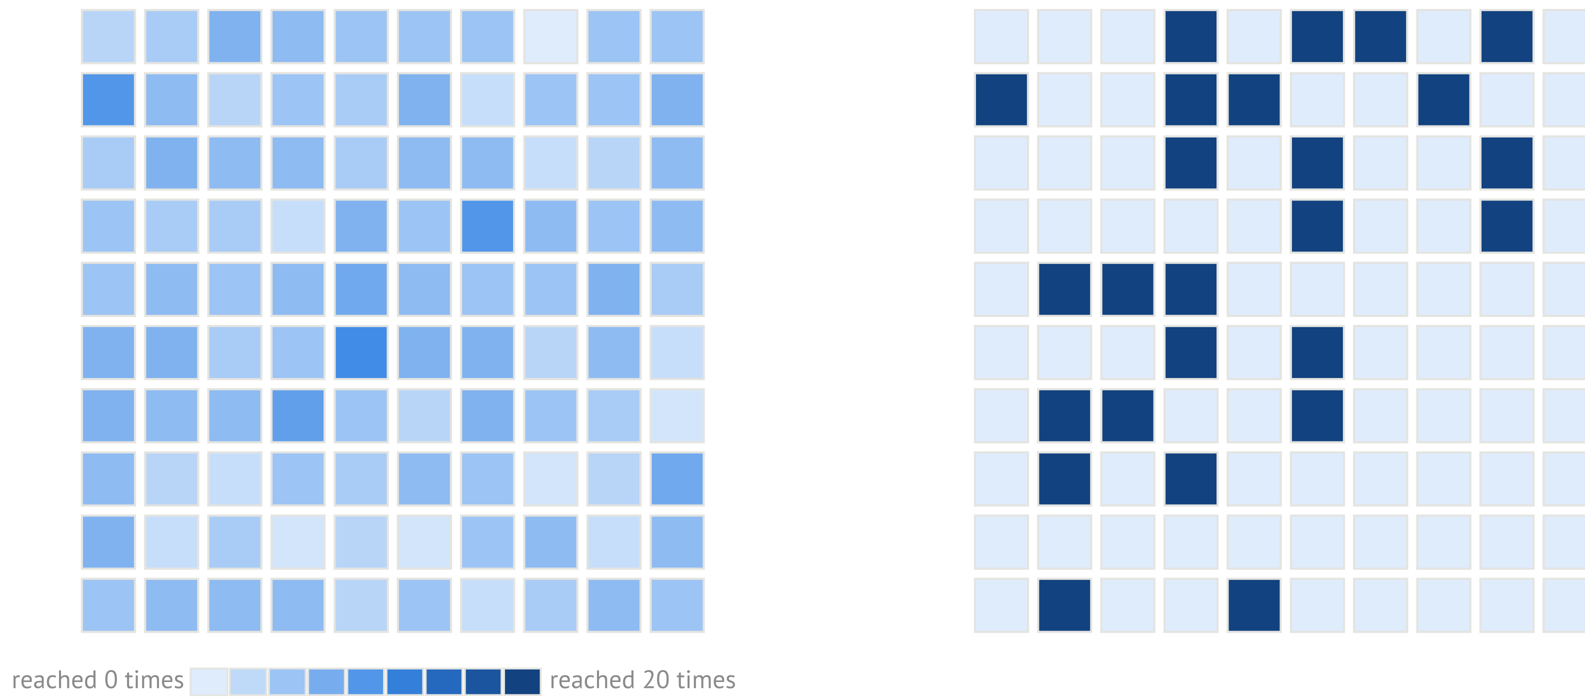
Two exposure schedules of identical size

$N = 100$, $\rho = 0.25$, 20 steps; each square is one agent, shaded by the number of times it was reached

`random`: a fresh audience each step

`fixed_random`: one audience throughout



every agent is reached about five times;
exposure is close to uniform

a quarter are reached at every step;
three quarters are never reached

In the model at $\rho_D = 0.25$ the exposure concentration $\mathrm{Var}_i(\sum_t g_i^D)$ is 38 under `random` and 7500 under `fixed_random`: the same number of exposures, distributed 200 times more unequally. Only the second amplifies.
