

$N = 100, \rho = 0.25, 20 \text{ steps}$; each square is one agent, shaded by the number of times it was reached

``random``: a fresh audience each step

every agent is reached about five times;
exposure is close to uniform

``fixed_random``: one audience throughout

a quarter are reached at every step;
three quarters are never reached

In the model at $\rho_D = 0.25$ the exposure concentration $\text{Var}_i(\sum_t g_i^D)$ is 38 under ``random`` and 7500 under ``fixed_random``:
the same number of exposures, distributed 200 times more unequally. Only the second amplifies.
